AppPAL for Android
Capturing and Checking Mobile App Policies

Joseph Hallett and David Aspinall

School of Informatics, University of Edinburgh

Abstract. It can be difficult to find mobile apps that respect your security and privacy. Businesses rely on employees enforcing company mobile device policies correctly. Users must judge apps by the information shown to them by the store. Only 17% of users pay attention to an apps permissions during installation [19] and most users do not understand how permissions relate to the capabilities of an app [30]. To address these problems, we present AppPAL: a machine-readable policy language for Android that describes precisely when apps are acceptable. AppPAL goes beyond existing policy enforcement tools, like Kirin [16], adding delegation relationships to allow a variety of authorities to contribute to a decision. AppPAL also acts as a "glue", allowing connection to a variety of local constraint checkers (e.g., static analysis tools, packager manager checks) to combine their results. As well as introducing AppPAL and some examples, we apply it to explore whether real users follow certain intended policies in practice, finding privacy preferences and actual behaviour are not always aligned, in the absence of a rigorous enforcement mechanism.

1 Introduction

Finding the right apps can be tricky. Users need to discover which are not going to abuse their data. This can be difficult as it isn't obvious how apps use the data each has access to. Consider a user attempting to buy a flashlight app. By searching the Play store the user is presented with a long list of apps. Clicking through each one they can find the permissions each requests but not the reasons why each was needed. They can see review scores from users but not from tools to check apps for problems and issues like SSL misconfigurations [17]. If they want to use the app at work will it break their employers rules for mobile usage?

App stores give some information about their apps; descriptions, screenshots and review scores. Android apps show a list of permissions when they're first installed. In Android Marshmallow apps will display permissions requests when the app first tries to access sensitive data (such as contacts or location information). Users do not understand how permissions relate to their device [19,42]. Ultimately the decision which apps to use and which permissions to grant must be made by the device user.

Some apps are highly undesirable. Many potentially unwanted programs (PUP) are being propagated for Android devices [43,41]. Employees are increasingly using their own phones for work. An employer may restrict which apps their

employees can use. The IT department may set a policy—a series of rules describing what kinds of apps may be used and how—to prevent information leaks. Some users worry apps will misuse their personal data—sending their address book or location to an advertiser without their permission. Such a user avoids apps which can access their location, or address book. They may apply their own personal security policies when downloading and running apps.

These policies can only be enforced by the users continuously making the correct decision when prompted about apps. An alternative is to write the policy down and make the computer enforce it. To implement this we use a logic of authorization—a language designed to express rules about permissible actions. The policy is written in the logic and enforced by checking the policy is satisfied.

We present AppPAL, an instantiation of Becker et al.'s SecPAL [6] with constraints[1] and predicates that allow us to decide which apps to run or install. The language allows us to reason about apps using statements from third parties. AppPAL allows us to enforce the policies on a device. We can express trust relationships amongst these parties and use constraints to do additional checks, such as using static analysis results. This lets us enforce more complex policies than existing tools such as Kirin [16] which are limited to permissions checks.

A user, Alice, may have rules she has to follow when using apps for work and her own policies when using apps at home in her private life. Using AppPAL we can write policies for work and home, and decide which policy to enforce using a user's location, or the time of day:

```
'alice' says App isRunnable
  if 'home-policy' isMetBy(App)
  where at('work') = false.
```

```
'alice' says App isRunnable
  if 'work-policy' isMetBy(App)
  where beforeHourOfDay('17') = true.
```

We can delegate policy specification to third parties or roles, and assign principals to roles:

```
'alice' says 'it-department' can-say 'work-policy' isMetBy(App).
'alice' says 'alice' can-act-as 'it-department'.
```

We can write policies specifying which permissions an app must or must not have by its app store categorization. For example it would be okay allowing a photography app access to the camera, but not to location data if the user doesn't want their photos geotagged.

```
'alice' says App isRunnable
  if 'permissions-policy' isMetBy(App).
'alice' says 'permissions-policy' isMetBy(App)
  if App isAnApp
  where
    category(App, 'Photography'),
    hasPermission(App, 'LOCATION') = false,
    hasPermission(App, 'CAMERA') = true.
```

[1] A constraint makes use of information checkable using information external to the language, such as the time of day or output of a static analysis tool.

There has been a great amount of work on developing app analysis tools for Android. Tools such as Stowaway [18] detect over-privileged apps. TaintDroid [15] and FlowDroid [1,33] can do taint and control flow analysis; sometimes even between app components. Other tools like QUIRE [11] can find privilege escalation attacks between entire apps. ScanDAL [31] and SCanDroid [21] help detect privacy leaks. Appscopy [20] searches for specific kinds of malware. Tools like DroidRanger [45] scan app markets for malicious apps. Various tools such as AppGuard [3], Dr. Android & Mr. Hide [29] or AppFence [27] can control the permissions or data an app can get. MalloDroid [17] looks for apps configured to use SSL incorrectly (for instance by not verifying hostnames or certificates). Many others exist checking and certifying other aspects of app behaviour.

AppPAL can act as a *"glue"* between static analysis tools and the app installation policies device owners are trying to enforce. This avoids creating tools with hard-coded fixed policies. For example a store might not want to sell apps with SSL errors or malicious apps as determined by their anti-virus. Using AppPAL we can combine tools for checking apps to implement the store's policies.

```
'play-store' says App isSellable
  if App isAnApp
  where mallodroidCheck(App) = true,
        mcafeeAVCheck(App) = true.
```

2 Enforcing A Policy At Work

An employee *Alice* works for *Emma*. Emma allows Alice to use her personal phone as a work phone but has some specific concerns.

- Alice shouldn't run any apps that can track her movements. Alice's workplace is at a secret location and it mustn't be leaked.
- Apps should come from a reputable source, such as the Google Play Store.
- Emma uses an anti-virus (AV) program by McAfee. It should check all apps before they're installed.

To ensure this policy is met Alice promises to follow it. She might even sign a document promising never to break the rules within the policy. This is error-prone—what if she makes a mistake or misses an app that breaks her policy. Alternately Emma's policy could be partially enforced using existing tools. *Google's Device Policy for Android* [23] could configure Alice's device to disallow apps from outside the Google Play Store and let Emma set the permissions granted to each app [37].

We could implement Emma's policy using existing tools (such as an AV checker, and a taint analysis tool like Flowdroid [1,33]) but it is a clumsy solution—they are not flexible. Each has to be configured separately to implement only part of the policy. If Emma changes her policy or Alice changes jobs she needs to recheck her apps and then alter or remove the software on her phone to ensure

compliance. It isn't clear what an app must do to be run, or what checks have been done if it is already running on the phone. The relationship between Alice (the user), Emma (the policy setter) and the tools Emma trusts to implement her policy isn't immediately apparent.

What happens when Alice goes home? Emma shouldn't be able to overly control what Alice does in her private life. Alice might not be allowed to use location tracking apps at work but at home she might want to (to meet friends, track jogging routes or find restaurants for example). Some mobile OSs, such as iOS and the latest version of Android, allow app permissions to be enabled and disable at run time. Can we enforce different policies at different times or locations?

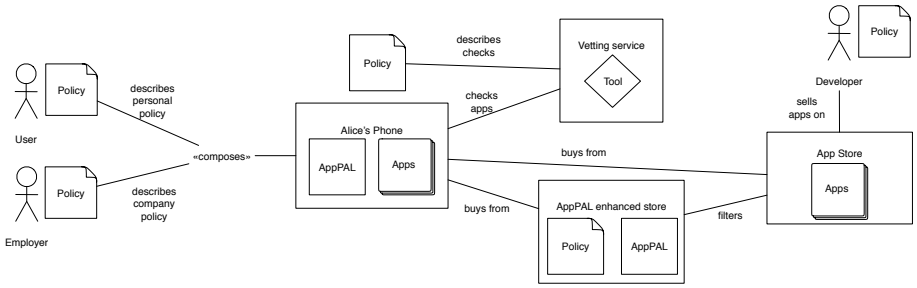

Fig. 1. Ecosystem of devices and stores with AppPAL.

We propose a change to the mobile ecosystem shown in Figure 1. People have policies which are enforced by AppPAL on their devices. They can be composed with policies from employers or others to create enhanced devices that ensure apps meet the policies of their owners. The device can make use of vetting services which run tools to infer complex properties about apps. Users can buy from enhanced stores which ensure the only apps they sell are the apps which meet the explicitly specified store policies. Developers could decide which stores to sell their apps in on the basis of policies about stores.

3 Expressing Policies In AppPAL

In Section 2 Alice and Emma had policies they wanted to enforce but no means to do so. Instead of using several tools to enforce Emma's policy disjointedly, we could use an authorization logic. In Figure 2 we give an AppPAL policy implementing Emma's app concerns on Alice's phone.

SecPAL is a logic of authorization for access control decisions in distributed systems. It has a clear and readable syntax, as well as rich mechanisms for delegation and constraints. SecPAL has already been used as a basis for other policy languages in areas such as privacy preferences [7] and data-sharing [2].

We present AppPAL as a modified form of SecPAL, targeting apps on mobile devices.

```
1  'alice' says 'emma' can-say inf
2    App isRunnable.
3
4  'emma' says App isRunnable
5    if 'no-tracking-policy' isMetBy(App),
6       'reputable-policy' isMetBy(App),
7       'anti-virus-policy' isMetBy(App).
8
9  'emma' says
10   'reputable-policy' isMetBy(App)
11      if App isBuyable.
12
13 'emma' says 'google-play' can-say
14   App isBuyable.
15 'emma' says 'anti-virus-policy' isMetBy(App)
16   if App isAnApp
17   where
18     mcafeeAVCheck(App) = true.
19
20 'emma' says 'no-location-permissions'
21   can-act-as 'no-tracking-policy'.
22
23 'emma' says
24   'no-location-permissions' isMetBy(App)
25     if App isAnApp
26     where
27       hasPermission(App, 'COARSE_LOCATION')=
             false,
28       hasPermission(App, 'FINE_LOCATION')=
             false.
```

Fig. 2. AppPAL policy implementing Emma's security requirements.

In line 2 Alice less Emma specify whether an `App` (a variable) `isRunnable`; she allows her to delegate the decision further (*`can-say inf`*). Emma specifies her concerns as policies to be met in line 4: if Emma is convinced all these are met then she will say the `App isRunnable`. In line 10 and line 14 Emma specifies that an app meets the `reputable-policy` if the `App isBuyable`; with `"google-play"` as the decider of what is buyable or not. Google is not allowed to delegate the decision further, i.e. Google is not allowed to specify Amazon as a supplier of apps as well. Emma specifies the `"anti-virus-policy"` in line 15 using a constraint. When checking the policy the `mcAfeeVirusCheck` should be run on the `App`. Only if this returns *`false`* will the policy be met. To specify the `"no-tracking-policy"` Emma says that the `"no-location-permissions"` rules implement the `"no-tracking-policy"` (line 21). Emma specifies this in line 24 by checking the app is missing two permissions.

Alice wants to install a new app (`com.facebook.katana`) on her phone. She needs to collect statements to show the app meets the `isRunnable` predicate. Namely:

- `"google-play"` *says* `"com.facebook.katana" isReputable.` Required to convince Emma the app came from a reputable source.
- `"emma"` *says* `"anti-virus-policy" isMetBy("com.facebook.katana").` She can obtain this by running the AV program on her app.
- `"emma"` *says* `"no-locations-permissions" isMetBy("com.facebook.katana").` Needed to show the App meets Emma's no-tracking-policy. Emma will say this if after examining the app the location permissions are missing.

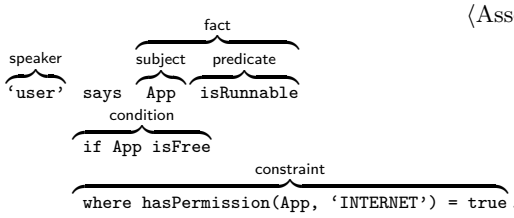
These last two statements require the checker to do some extra checks to satisfy the constraints. To get the second statement AppPAL must run the AV program on her app and check the result. The results from the AV program may change

with time as it's signatures are updated; so the checker must re-run this check every time it wants to obtain the statement connected to the constraint. For the third statement the AppPAL checker needs to examine the permissions of the app. It could do this by looking in the `MANIFEST.xml` inside the app itself, or through the Android package manager if it is running on a device.

We could also imagine Emma wanting a personalised app store where all apps sold meet her policy. With AppPAL this can be implemented by taking an existing store and selectively offering only the apps which will meet the user's policy. This gives us a *filtered store* which, from an existing set of apps, we get a personalised store that only sells apps that meet a policy.

4 AppPAL

AppPAL is implemented as a library for Android and Java. The parser is implemented using ANTLR4. AppPAL's syntax is inherited from SecPAL [6] (shown in Figure 3).



⟨Assertion⟩ := ⟨E⟩ **says** ⟨Fact⟩
(**if** (⟨Fact⟩**,**)+)?**.**
(**where** ⟨Constraint⟩)?
⟨Fact⟩ := ⟨E⟩ (**isRunable** | ...)
| ⟨E⟩ **can-say inf**? ⟨Fact⟩
| ⟨E⟩ **can-act-as** ⟨E⟩
⟨E⟩ := **Variable** | **'constant'**

Fig. 3. Structure and simplified grammar of an AppPAL assertion.

In SecPAL the precise nature of predicates and constraints is left open. In instantiating SecPAL, AppPAL makes the predicates and constraints explicit. AppPAL policies can make use of the predicates and constraints in Table 1. Additional predicates can be created in the policy files, however constraints are implemented individually. For example on Android the `hasPermission` constraint uses the Android package manager to check what permissions an app requests, but the Java version uses the Android platform tools to check.

Splitting the decision about whether an app is runnable into a series of policies that must be met gives us flexibility in how the decision is made. It allows us to describe multiple means of making the same decision, and provide backup routes when one fails. Some static analysis tools are not quick to run. Even taking minutes to run a battery draining analysis can be undesirable: if a user wants to download an app quickly they may not be willing to wait to check that a policy is met.

In Section 2 and Section 3 we described a *no-tracking-policy* to prevent a user's location being leaked. In Emma's policy we checked this using the app's permissions; if the app couldn't get access to the GPS sensors (using

Name	Description
App `isRunnable`	Says an app can be run.
App `isInstallable`	Says an app can be installed.
App `isAnApp`	Tells AppPAL that an app exists.
Policy `isMetBy`(App)	Used to split policies into smaller components.
`hasPermission`(App, Permission)	Constraint to check if an app has a permission.
`beforeHourOfDay`(time)	Constraint used to check the time.
Tool`Check`(App, Property)	Constraint to run an analysis tool on an app.

Table 1. AppPAL predicates and constraints.

the permissions) then it met this policy. Some apps may want to access this data, but may not leak it. We could use a taint analysis tool to detect this (e.g. FlowDroid [1,33]). Our policy now becomes:

```
'emma' says 'no-locations-permissions'
  can-act-as 'no-tracking-policy'.

'emma' says 'no-locations-permissions' isMetBy(App)
  if App isAnApp
  where
    hasPermission(App, 'ACCESS_FINE_LOCATION') = false,
    hasPermission(App, 'ACCESS_COARSE_LOCATION') = false.

'emma' says 'location-taint-analysis'
  can-act-as 'no-tracking-policy'.

'emma' says 'location-taint-analysis' isMetBy(App)
  if App isAnApp
  where
    flowDroidCheck(App, 'Location', 'Internet') = false.
```

Sometimes we might want to use location data. For instance Emma might want to check that Alice is at her office. Emma might track Alice using a location tracking app. Provided the app only talks to Emma, and it uses SSL correctly (using MalloDroid [17]) she is happy to relax the policy.

```
'emma' says 'relaxed-no-tracking-policy' canActAs 'no-tracking-policy'.
'emma' says 'relaxed-no-tracking-policy' isMetBy(App)
  if App hasCategory('tracking')
  where
    mallodroidSSLCheck(App) = false,
    connectionsCheck(App, '[https://emma.com]') = true.
```

This gives us four different ways of satisfying the *no-tracking-policy*: with permissions, with taint analysis, with a relaxed version of the policy, or by Emma directly saying the app meets it. When we come to check the policy if any of these ways give us a positive result we can stop our search.

4.1 Policy Checking

AppPAL has the same policy checking rules as SecPAL [6]. AppPAL uses an assertion context of known facts and rules, as well as facts deduced while checking. While Becker et al. used a DatalogC based checking algorithm, we have implemented the rules directly in Java as no DatalogC library is currently available for Android. Pseudo-code is shown in Figure 4.

On a mobile device memory is at a premium. We would like to keep the assertion context as small as possible. For some assertions (like `isAnApp`) we derive them by checking the arguments at evaluation time. This gives us greater control of the evaluation and how the assertion context is created. For example, when checking the `isAnApp` predicate; we can fetch the assertion that the subject is an app based on the app in question. When delegating we will also be able to request facts from the delegated party dynamically; though implementing this is future work.

```
def evaluate(ac, rt, q, d)
  return rt[q, d] if rt.contains q, d
  p = cond(ac, rt, q, d)
  if p.isValid then
    return (Proven, rt.update q, d, p)
  p = canSay_CanActAs(ac, rt, q, d)
  if p.isValid then
    return (Proven, rt.update q, d, p)
  else
    return (Failure, rt.update q, d, Failure)

def cond(ac, rt, q, d)
  ac.add q.fetch if q.isFetchable
  ac.assertions.each do |a|
    if (u = q.unify a.consequent) &&
       (a = u.sub a).variables == none
      return checkConditions ac, rt, a, d
  return Failure
```

```
def canSay_CanActAs(ac, rt, q, d)
  ac.constants.each do |c|
    if c.is_a :subject
      p = canActAs ac, rt, q, d
      return Proven if p.isValid
    elsif c.is_a :speaker
      p = canSay ac, rt, q d
      return Proven if p.isValid
  return Failure

def checkConditions(ac, rt, a, d)
  getVarSubs(a,ac.constants).each do |s|
    sa = s.sub a
    if sa.antecedents.all
        { |a| evaluate(ac, rt, a, d).isValid }
      p = evaluateC sa.constraint
      return Proven if p.isValid
  return Failure
```

Fig. 4. Partial-pseudocode for AppPAL evaluation.

4.2 Benchmarks

When AppPAL runs on a mobile phone apps should be checked as they are installed. Since policy checks may involve inspecting many rules and constraints one may ask whether the checking will be acceptably fast. Downloading and installing an app takes about 30 seconds on a typical Android phone over wifi. If checking a policy delays this even further a user may become annoyed and disable AppPAL.

The policy checking procedure is at its slowest when having to delegate repeatedly; the depth of the delegation tree is the biggest factor for slowing the

search. Synthetic benchmarks were created to check that the checking procedure performed acceptably. Each benchmark consisted of a chain of delegations. The *1 to 1* benchmark consists of a repeated delegation between all the principals. In the *1 to 2* benchmark each principal delegated to 2 others and in the *1 to 3* benchmark each principal delegated to 3 others. These benchmarks are reasonable as they model the slowest kinds of policies to evaluate—though worse ones could be designed by delegating even more.

For each benchmark we controlled the number of principals in the policy file: as the number of principals increased so did the size of the policy. The results are shown in Figure 5. We have only used a few delegations per decision when describing hypothetical user policies. We believe the policy checking performance of AppPAL is acceptable as unless a policy consists of hundreds of delegating principals the overhead of checking an AppPAL policy is negligable.

Delegations	Principals	Time (s)
1 to 1	10	0.01
1 to 1	100	1.00
1 to 1	500	20.90
1 to 1	1000	88.73
1 to 2	10	0.01
1 to 2	100	0.43
1 to 2	500	7.36
1 to 2	1000	27.47
1 to 3	10	0.01
1 to 3	100	0.24
1 to 3	500	3.99
1 to 3	1000	15.28

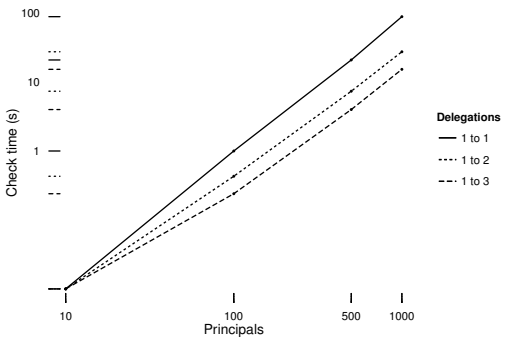


Fig. 5. Benchmarking results on a Nexus 4 Android phone.

5 Measuring Policy Compliance

Throughout we have asserted that users have policies and that there is a need for policy enforcement tools. Corporate mobile security bring your own device (BYOD) policies have started appearing and NIST have issued recommendations for writing them [38,40]. In a study of 725 Android users, Lin et al. found four patterns that characterise user privacy preferences for apps [35] demonstrating a refinement of Westin's privacy segmentation index [32]. Using app installation data from Carat [36,12] we used AppPAL to find the apps satisfying each policy Lin et al. identify and measure the extent that each user was following a policy.

Lin et al. identified four types of user. The *Conservative* (C) users were uncomfortable allowing an app access to any personal data for any reason. The *Unconcerned* (U) users felt okay allowing access to most data for almost any reason. The *Advanced* (A) users were comfortable allowing apps access to location

data but not if it was for advertising reasons. Opinions in the largest cluster, *Fencesitters* (F), varied but were broadly against collection of personal data for advertising purposes. We wrote AppPAL policies to describe each of these behaviours as increasing sets of permissions. These simplify the privacy policies identified by Lin et al. as we do not take into account the reason each app might have been collecting each permission. Using AppPAL we could write more precise rules if we could determine why each permission was requested. Lin et al. used Androguard [13] as well as manual analysis to determine the precise reasons for each permission [35].

Policy	C	A	F	U
GET_ACCOUNTS	✗	✗	✗	✗
ACCESS_FINE_LOCATION	✗	✗	✗	
READ_CONTACT	✗	✗	✗	
READ_PHONE_STATE	✗	✗		
SEND_SMS	✗	✗		
ACCESS_COARSE_LOCATION	✗			

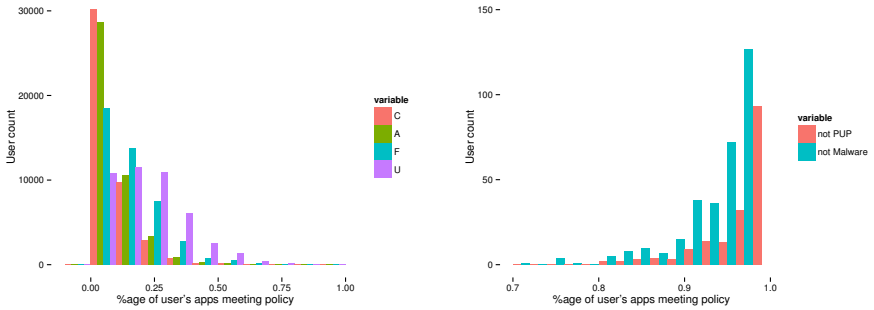
It is also interesting to discover when people install apps classified as malware. McAfee classify malware into several categories, and provided us with a dataset of apps classified as malware and PUP. The *malicious* and *trojan* categories describe traditional malware. Other categories classify PUP such as aggressive adware. Using AppPAL we can write policies to differentiate between different kinds of malware, characterising users who allow dangerous apps and those who install poor quality ones.

```
'user' says 'mcafee' can-say
  'malware' isKindOf(App).
'mcafee' says 'trojan' can-act-as 'malware'.
'mcafee' says 'pup' can-act-as 'malware'.
```

If a user is enforcing a privacy policy we might also expect them to install less malware. We can check this by using AppPAL policies to measure the number of malwares each user had installed.

We now want to test how closely user behavior follows policies. Installation data was taken from a partially anonymized[2] database of installed apps captured by Carat [36]. By calculating the hashes of known package names we see who installed what. The initial database has over 90,000 apps and 55,000 users. On average each Carat user installed around 90 apps each; 4,300 apps have known names. Disregarding system apps (such as `com.android.vending`) and very common apps (Facebook, Dropbox, Whatsapp, and Twitter) we reduced the set to an average of 20 known apps per user. To see some variations in app type, we considered only the 44,000 users who had more than 20 known apps. Using this data, and the apps themselves taken from the Google Play Store and Android Observatory [4], we checked which apps satisfied which policies.

[2] Users are replaced with incrementing numbers, app names are replaced with hashes to protect sensitive names.



(a) Uptake of Lin et al.'s policies.

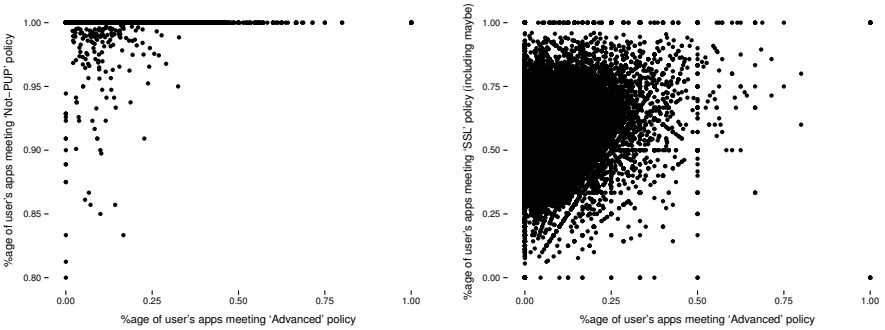
(b) Uptake of malware and PUPs.

Fig. 6. Policy compliance graphs. Each histogram shows the number of users who followed a policy to a certain extent. Users who installed no malware have been omitted from Figure 6(b).

Figure 6(a) shows that very few users follow Lin et al.'s policies most of the time. Whilst the AppPAL policy we used was a simplified version of Lin et al.'s policy, it suggests that there is a disconnect between users privacy preferences and their behaviour (reminiscent of the *privacy paradox*); assuming the user population studied by Lin et al. behave similarly to data from the Carat study. A few users, however, did seem to be installing apps meeting these policies most of the time. This suggests that while users may have privacy preferences the majority are not attempting to enforce them. Policy enforcement tools, like AppPAL, can help users enforce their own policies which they cannot do easily using the current ad hoc, manual means available to them.

We found 1% of the users had a PUP or malicious app installed. Figure 6(b) shows that infection rates for PUPs and malware is low; though a user is 3 times more likely to have a PUP installed than malware. Users who were complying more than half the time with the conservative or advanced policies complied with the malware or PUP policies fully (Figure 7(a)). This suggests that policy enforcement is worthwhile: users who can enforce policies about their apps experience less malware.

The *MalloDroid* tool [17] can scan apps for SSL misconfigurations. SSL misconfigurations are dangerous as they can undermine any privacy guarantees that SSL/TLS usage gives. MalloDroid can scan for several misconfigurations, and distinguishes cases where the app is definitely misconfigured from those where there is some doubt. We set up AppPAL to use MalloDroid results as a constraint and measured the percentage of apps each Carat user had installed that did not have issues or suspected issues when scanned with MalloDroid. Users who were complying with the advanced policy were no better at avoiding apps with SSL errors than any other users, see Figure 7(b). This emphasizes that AppPAL can help enforce complex policies that cannot be checked for without additional tools.



(a) Advanced and non-PUP policies. (b) Advanced and SSL policies.

Fig. 7. Compliance with the advanced policy and the non-PUP and SSL policies. Each data-point represents a user. In (a) we see that users who followed the Advanced policy more than 50% of the time did not install any malware. In (b) we see that even users who followed the Advanced policy were no better at avoiding apps with SSL problems than any other users.

There are some limitations in this investigation: firstly, we do not have the full user purchase history, and we can only find out about apps whose names match those in available databases. So a user may have apps installed that break the policy without us knowing. Secondly recently downloaded apps used for experiment may not be the same version that users had, in particular, their permissions may differ. Permissions tend to increase in apps over time [44]; so a user may be more conservative than our analysis suggests. Finally, as mentioned, we have compared a different set of users to the ones Lin et al. looked at. We plan to do a more comprehensive user study in the future that investigates AppPAL in use with different communities.

6 Related Work

Authorization logics have been successfully used to enforce policies in several other domains. The earliest such logic, PolicyMaker [10], was general, if undecidable. Logics that followed like KeyNote [9] and SPKI/SDSI [14] looked at public key infrastructure. The RT-languages [34] were designed for credential management. Cassandra [8] was used to model trust relationships in the British national health service.

SELinux is used to describe policies for Linux processes, and for access control (on top of the Linux discretionary controls). It was ported to Android [39] and is used in the implementation of the permissions system. SELinux describes the capabilities (in terms of system calls and file access) of processes, it cannot describe app installation policies or delegation relationships. Google also offer the *Device Policy for Android* app. This lets businesses configure company owned devices to be trackable, remote lockable, set passwords and sync with their servers.

It cannot be used to describe policies about apps, or describe trust relationships, however.

The SecPAL language is designed for access control in distributed systems. We picked SecPAL as the basis for AppPAL because it is readable, extensible, and is a good fit for the mobile ecosystem setting [26]. It has also been used to describe data usage policies [2] and inside Grid data systems [28]. Other work on SecPAL has added various features such as existential quantification [5] and the DKAL family of policy languages [24,25]. DKAL contains more modalities than *says*, which lets policies describe actions principals carry out rather than just their opinions. For example in AppPAL a user might *say* an app is installable if they would install it (`"user" says App isInstallable`). In DKAL they can describe the conditions that would force them to install it (`"user" installs App`). With DKAL we can guarantee that the action was completed, whereas in AppPAL we do not know if the user actually installed a particular app. We chose to use SecPAL as the basis for AppPAL as we did not need the extra features DKAL added to express app installation policies. If, in future work, we need additional modalities AppPAL could be extended to support additional DKAL features as SecPAL has been shown to be a subset of the DKAL language.

Kirin [16] is a policy language and tool for enforcing app installation policies to prevent malware. Policy authors can specify combinations of permissions and broadcast events that should not appear together. For example to stop malware sending premium rate text messages, we prevent an app having both the `SEND_SMS` and `WRITE_SMS` permissions.

```
restrict permission [SEND_SMS] and permission [WRITE_SMS]
```

By analyzing apps which broke their policies Enck et al. found vulnerabilities in Android, but were ultimately limited by being restricted to permissions and broadcast events.

This approach could help identify malware, but it is less suitable for detecting PUPS. The behaviours and permissions PUP displays aren't necessarily malicious. One user may not want apps which need in-app-purchases to play, but another may enjoy them. With Kirin we are restricted to permitting or allowing apps. AppPAL can describe more scenarios than just allow or forbid, and use more app information than just permissions, such as constraints and static analysis results. By allowing delegation relationships we can understand the provenance and trust relationships in these rules.

7 Conclusions and Further Work

We have presented AppPAL: an authorization logic for describing app installation policies primarily designed to help achieve security and privacy objectives but which can also *lock down* devices in other ways, e.g. restricting the use of certain apps while at work. We showed how static analysis tools can be integrated into AppPAL to check for complex properties and to act as a glue between different policies.

AppPAL currently runs either an Android app or a Java program. Further work is needed to tightly integrate AppPAL into Android. One way to integrate AppPAL on Android would be as a *required checker*: a program that checks all apps before installation. Google uses the required checker API to check for known malware and jailbreak apps. We would use AppPAL to check apps meet policies before installation. The API is protected, however, and it would require the phone to have a custom firmware. This is undesirable as it would make AppPAL difficult to install for most users, and negate the other security enhancements (such as timely updates and patches) provided by the standard Android system. Alternatively, AppPAL could be integrated as a service to reconfigure app permissions. Android Marshmallow has an iOS like permissions model where permissions can be granted and revoked at any time. These will be manually configurable by the user through the settings app. We can imagine AppPAL working to reconfigure these settings (and set their initial grant or deny states) based on a user's policy, as well as the time of day or the user's location. A policy could deny notifications while a user is driving, for example, by checking if they are using Android Auto [22] (an app to interact with a car's center console) or moving along a road at high speed.

Developing, and testing, policies for users is a key next step. Here we described a policy being specified by a user's employer. For most end-users writing a policy in a formal language is too much work. Ad-blocking software works by users subscribing to filter policies written by experts. EasyList is a popular choice and they offer many policies for specific use-cases[3]. We can imagine a similar scheme working well for app installation policies. Users subscribe to different policies by experts (examples could include no tracking apps, nothing with adult content, no spammy in-app-purchase apps). Optionally they can customize them further.

We might attempt to learn policies from existing user's behavior. Given app usage data, from a project like Carat [36], we could identify security conscious users. If we can infer these users policies we may be able to describe new policies that the less technical users may want. Given a set of apps one user has already installed, we could learn policies about what their personal installation policy is. This may help stores show users apps they're more likely to buy, and users apps that already behave as they want.

AppPAL is a powerful language for describing app installation policies. It gives us a framework for describing and evaluating policies for Android apps. The work provides new, rigorous, ways for machines to enforce user's and device-owner's rules about how apps should behave. These policies can be enforced more reliably, and with less interaction from person operating the device.
